We investigate the uniaxial-pressure dependence of resistivity for $URu_{2-x}Fe_xSi_2$ samples with $x = 0$ and 0.2, which host a hidden order (HO) and a large-moment antiferromagnetic (LMAFM) phase, respectively. For both samples, the elastoresistivity ζ shows a seemingly divergent behavior above the transition temperature T_0 and a quick decrease below it. We find that the temperature dependence of ζ for both samples can be well described by assuming the uniaxial pressure effect on the gap or certain energy scale except for $\zeta_{(110)}$ of the $x = 0$ sample, which exhibits a nonzero residual value at 0 K. We show that this provides a qualitative difference between the HO and LMAFM phases. Our results suggest that there is an in-plane anisotropic response to the uniaxial pressure that only exists in the hidden order state without necessarily breaking the rotational lattice symmetry.

The hidden order (HO) in URu_2Si_2 has raised great interests in the last three decades. [1–6] The mystery is that a large specific-heat anomaly is observed at the HO transition temperature ($T_0 = 17.5$ K), unambiguously suggesting a second-order transition, but no consensus on the order parameter has yet been reached. An antiferromagnetic (AFM) order [7] has been found at T_0, but the ordered moment is too small to account for the large entropy released by the HO phase. Recently, a compelling scenario for the origin of the HO has been proposed based on the in-plane rotational symmetry breaking. [8–11] Accordingly, the HO order parameter should spontaneously break the four-fold symmetry and a tetragonal-orthorhombic structural change is expected at T_0, which is similar to the nematic order observed in iron-based superconductors. [12–16] However, more recent studies suggest that there is no evidence for either the structural transition or nematic fluctuations. [17–20] What seems to be consensus now is that URu_2Si_2 indeed shows in-plane anisotropic properties under uniaxial strain or magnetic field. [8,10,20] It is thus crucial to ask whether there is some kind of anisotropy that is unique to the HO, and if there is, whether such anisotropy can exist without breaking the rotational symmetry.

In the URu_2Si_2 system, the so-called large-moment antiferromagnetic (LMAFM) phase has been found to be intimately related to HO. In this phase, the magnetic order has the same ordering vector as the AFM order in HO but with much larger ordered moment. The first-order transition from the HO to the LMAFM phase is first found in URu_2Si_2 under hydrostatic pressure [21–26] and later in Fe-doped samples. [27–31] Surprisingly, transport and thermodynamic properties have very similar behaviors in both phases although their order parameters are presumably different. Moreover, the Fermi surfaces of these two phases and magnetic excitations are rather similar. [26,32,33] The crossover between these two phases has been referred to as "adiabatic continuity" since they are intimately related. [23] It is thus intriguing to check the anisotropic behaviors in both the HO and LMAFM phases to find out the unique one of the former, if it does exist.

In this Letter, we study the uniaxial elastoresistance ζ in $URu_{2-x}Fe_xSi_2$ ($x = 0$ and 0.2). The divergent behavior of ζ above T_0 is observed in both samples and the amplitude of ζ shows no significant difference between the samples. We provide a simple explanation based on the uniaxial pressure effect on certain energy scales and thus rule out the existence of nematic fluctuations. Interestingly, a large residual ζ at 0 K along the (110) direction is only observed in the $x = 0$ sample, which cannot be described by the above scenario. Our results thus provide a unique property associated with the HO state, which does not necessarily break the lattice rotational symmetry.

Single crystals of $URu_{2-x}Fe_xSi_2$ were grown by the Czochralski method in a tetra-arc furnace with a continuously purified Ar atmosphere and subsequently annealed at 900℃ under ultrahigh vacuum for ten days. The samples were cut into thin plates by a wire saw machine with the desired directions determined by the Laue technique. With the tetragonal notation, the (100) direction corresponds to a or b axis of the lattice while the (110) direction corresponds to the diagonal direction of a and b axes. The elastoresistance was measured by a home-made uniaxial-pressure device based on piezobender as reported previously.[15,16] The uniaxial pressure is defined to be positive when the sample is compressed. Since the resistance linearly depends on p, we define $\zeta = R(0)^{-1}d\Delta R/dp$, where $R(0)$ is the resistance at zero pressure and $\Delta R = R(p) - R(0)$.[15,16] We note that only data from selected samples will be shown below while we have measured several samples for each doping along both the (100) and (110) direction to make sure the credibility of the results. For all the samples measured, the maximum uniaxial pressure applied is smaller than 10 MPa. Hydrostatic pressure resistance measurements were performed in a piston/cylinder-type high-pressure cell with silicone oil as pressure transmitting medium. Pressure is determined by the pressure-dependent superconducting transition temperature T_C of Pb[34] that is placed in the Teflon capsule together with the sample. In the following, we employ p and P to denote the uniaxial pressure and hydrostatic pressure, respectively.

Fig. 1. (a) Temperature dependence of ζ for URu_2Si_2. The solid lines are fitting results by the Curie–Weiss-like function, as described in the text. (b) Temperature dependence of $\Delta\zeta$ (circles) and $|A_{2\phi}|/V$ (sold line)[8] for URu_2Si_2. The data around T_0 for $\Delta\zeta$ have been omitted for clarification.

Figure 1(a) shows the temperature dependence of ζ for

URu_2Si_2, with the uniaxial pressure p applied along the (100) and (110) directions. For both directions, ζ exhibits the same temperature dependence. The sharp peak at T_0 is associated with the change of T_0 under pressure. Similar to previous reports,[10] the data above T_0 can be fitted by a Curie–Weiss-like function $A/(T - T') + y_0$, where A, T' and y_0 are all temperature-independent parameters. The values of T' for both fittings are about 6 K, which are well below T_0. It should be pointed out that T' can change significantly for different temperature fitting ranges.

A significant difference between $\zeta_{(110)}$ and $\zeta_{(100)}$ is that the former has a finite value at 0 K while the latter tends to go to zero, as shown in Fig. 1(a). This difference has also been observed in the uniaxial strain dependence of the elastoresistivity.[10] Since α, the ratio of $\zeta_{(110)}/\zeta_{(100)}$ above T_0 is independent of temperature and close to 2 for these two samples, we can distinguish the anisotropy of the elastoresistance in the HO state from that above T_0 by calculating $\Delta\zeta = \alpha\zeta_{(100)} - \zeta_{(110)}$, as shown in Fig. 1(b). We note that although α may depend on the samples due to their quality and the precision in determining the cross section in our method,[15] $\Delta\zeta$ above T_0 can be reduced to zero with proper choice of α. On the other hand, $\Delta\zeta$ always shows a residual value at 0 K no matter what value of α is chosen. Its temperature dependence seems to be similar to that of the two-fold oscillation amplitude $|A_{2\phi}|/V$ observed in torque measurements.[8]
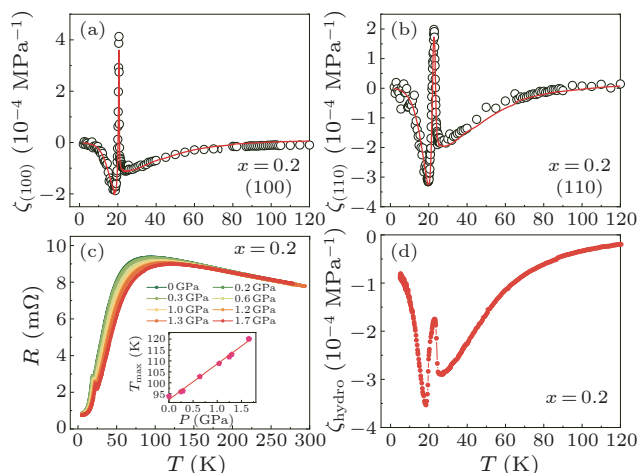

Fig. 2. (a) and (b) The temperature dependence of $\zeta_{(100)}$ and $\zeta_{(110)}$, respectively, for the $x = 0.2$ sample. The solid lines are the calculated results of Eq. (2) with $\delta = 6.5 \times 10^{-5}$ and 1.15×10^{-4} for the (100) and (110) directions, respectively. (c) The temperature dependence of the resistance for the $x = 0.2$ sample under different hydrostatic pressures. The inset shows the change of T_{max} under pressure. (d) The temperature dependence of ζ_{hydro} for the $x = 0.2$ sample.

We will demonstrate that the residual $\Delta\zeta$ at 0 K represents the true anisotropic properties of the HO state. Figures 2(a) and 2(b) show the temperature dependence of $\zeta_{(100)}$ and $\zeta_{(110)}$, respectively, for the $x = 0.2$ sample. The overall features are similar to those in the $x = 0$ sample, including the seemingly divergent behavior above T_0, the sharp peak at T_0 and the quick decrease below T_0.

However, unlike the $x = 0$ sample, ζ tends to go to zero for both directions, which results in a zero $\Delta\zeta$ at 0 K. Since the $x = 0.2$ sample has the LMAFM ground state,[31] the nonzero $\Delta\zeta$, i.e., the nonzero $\zeta_{(110)}$ at 0 K, should be a unique property of the HO.

Before further discussing the nonzero $\zeta(110)$ at 0 K, we address the behaviors of ζ above T_0 first. Previous studies have invoked nematic fluctuations to account for the increase of elastoresistivity with decreasing temperature,[10] which would require the breaking of the in-plane rotational symmetry in the HO state. It was later pointed out that the change of resistivity in URu$_2$Si$_2$ under hydrostatic pressure shows very similar behaviors with that under uniaxial strain, which was attributed to the volume effect.[20] Here we also carried out the resistivity measurements on the $x = 0.2$ sample under hydrostatic pressure, as shown in Fig. 2(c). Accordingly, we can define $\zeta_{\mathrm{hydro}} = R(0)^{-1}\Delta R/\Delta P$, which is shown in Fig. 2(d). Similar to URu$_2$Si$_2$,[20] the overall features and values are comparable with the uniaxial results, which is against the existence of nematic fluctuations. Even if the elastoresistivity above T_0 does come from nematic fluctuations, nematicity should play little role in the formation of the HO since it results in similar behaviors of ζ above T_0 for the LMAFM state.

In fact, we can give a simple explanation for the temperature dependence of ζ above T_0. As seen in Figs. 2(a) and 2(b), ζ becomes significant only below about 80 K. It is well known that the resistivity across this temperature is associated with the coherence temperature T^*,[35–37] so the quick drop of the resistivity may take the form $f(T/T^*)$. While there is no analytical function to describe the data, the quick drop of the resistivity suggests that it may have an exponential component. We thus introduce the following equation to fit the data,

$$R = \frac{A}{T}e^{-T^*/T} + R_0, \tag{1}$$

where A and R_0 are temperature-independent parameters, and T^* is the coherent temperature or at least close to it. As shown in Fig. 3(a), this equation can well describe the quick drop of the resistivity. In addition, if the resistivity takes the general form $f(T/T^*)$, the resistivity of the $x = 0$ and 0.2 samples can be normalized to T^*, which is indeed the case as shown in Fig. 3(b). The above results thus clearly demonstrate that the temperature dependence of the resistivity between T_0 and T^* is dominated by a general function $f(T/T^*)$.

Supposing that the change of T^* by a small pressure p leads to $T^* \to (1 + \delta)T^*$, the change of the resistivity is thus $f[T/(1 + \delta)T^*] - f(T/T^*)$, which is approximately equal to $f[(1-\delta)T/T^*] - f(T/T^*)$ as δ is small. Therefore, we can simply change the temperature T to $(1+\delta)T$ in the $R_0(T)$ data at zero pressure to have $R_p(T') = R_0[(1+\delta)T]$ under pressure. The value of R_p at temperature T is thus approximately to $R_0[(1 - \delta)T]$. According to the above analysis, the elastoresistance takes the following form:

$$\zeta^* = \frac{R_0[(1-\delta)T] - R_0(T)}{R_0(T)}. \tag{2}$$

where the unit of ζ^* is set to MPa^{-1}. It is interesting to note that the similar method has been used in removing the phonon contribution of the specific heat if its temperature dependence is only associated with the Debye temperature.[38–40] We also note that Eq. (2) also suggests a close connection between ζ and dR/dT according to its Taylor expansion (see the Supplemental Material for details).
Fig. 3. (a) Temperature dependence of the normalized resistance $R/R(200\,K)$. The solid lines are the fitted results of Eq. (1). (b) Normalized resistivity according to T^*. (c) and (d) The temperature dependences of $\zeta(100)$ and $\zeta(110)$ for URu$_2$Si$_2$, respectively. The solid lines are the calculated results of Eq. (2) with $\delta = 5 \times 10^{-5}$ and 6×10^{-5} for the red and green lines in (c), respectively, and 1.05×10^{-4} in (d).

It is clear that this method describes the temperature dependence of ζ above T_0 of the $x = 0.2$ sample for both the (100) and (110) directions, as shown in Figs. 2(a) and 2(b), respectively. It is surprising is that ζ below T_0 and even right at the transition can also be well described by Eq. (2). According to Eq. (2), the value of δ is associated with the relative change of T^* under the uniaxial pressure. Treating T^* roughly as $T_{\max}$, which corresponds to the temperature where the resistance is maximum, the value of $\delta T_{\max}/p$, where p is 1 MPa, should be close to $dT_{\max}/dp$. We find that $\delta T_{\max}/p$ is about 6.1 and 10.8 K/GPa for the (100) and (110) directions, respectively, which are indeed close to the value of $dT_{\max}/dP \sim 16$ K/GPa under the hydrostatic pressure, as shown in the inset of Fig. 2(c).

Now we apply the above analysis to the uniaxial elastoresistivity in the $x = 0$ sample, as shown in Figs. 3(c) and 3(d). Using Eq. (2), the data above T_0 can be again nicely replicated. The values of $\delta T_{\max}/p$ for the (100) and (110) directions are about 4.6 and 8 K/GPa, respectively, which are again close to the value of $dT_{\max}/dP$ under the hydrostatic pressure ($\sim$14 K/GPa).[41] Different from the $x = 0.2$ sample, Eq. (2) cannot describe $\zeta_{(100)}$ for the whole temperature range using just one δ. Instead, we have to change the value of δ to reproduce $\zeta_{(100)}$ below T_0, which seems to be associated with the change of the gap in the HO state under pressure (see the Supplemental Material

for details).[31,41] However, we can never describe $\zeta_{(110)}$ below T_0 by Eq. (2) due to the existence of the residual 0-K value. This again demonstrates the unique connection between $\Delta\zeta$ and the HO.

Our results show that the large nonzero value of $\zeta_{(110)}$ at 0 K represents the intrinsic anisotropic response of the resistivity to the uniaxial pressure in the HO state. We note that this behavior is different from that of the uniaxial-pressure-induced AFM moment, which shows no difference between the (100) and (110) directions.[42] It is commonly believed that the resistivity below T_0 can be described by gap functions for both the HO and LMAFM phases.[31,41] This is consistent with Eq. (2) as the gap Δ in the functions is always coupled to the temperature as Δ/T (see the Supplemental Material for details). Our results of $\zeta_{(110)}$ for the $x = 0$ sample suggest that there should exist a component of the resistivity, which can be only invoked under uniaxial pressure along the (110) direction and is beyond any kind of gap functions.[31,41] We suggest that the unique information of the HO state may be only revealed under uniaxial pressure.

Previous studies have shown some quantitative differences between the HO and LMAFM states.[23,24,30,31] Our results show that the HO state can be *qualitatively* distinguished from the LMAFM state by their response to the uniaxial pressure along the (110) direction. It is particularly needed to emphasize that contrary to some previous results,[8–11] the above uniaxial-pressure-induced anisotropy does not require breaking the rotational symmetry.[17–20] We note that in the case when the sample is not free-standing, the local residual stress induced by, e.g., glue may effectively provide uniaxial pressure or strain to give rise to results that should be absent at zero strain.[43] This could explain the similar behaviors between $\Delta\zeta$ and $|A_{2\phi}|/V$ in Fig. 1(b). The existence of nematic fluctuations can also be ruled out by the facts that ζ above T_0, first, shows similar behaviors with that under the hydrostatic pressure, and second, can be simply reproduced by Eq. (2), which connects the origin of the elastoresistance with a trivial pressure effect on some kind of energy scale. Even nematic fluctuations are indeed present, their role on the HO must be neglected since ζ has similar amplitude for both the HO and LMAFM states. Our results may thus suggest a somehow strange property of the HO. On the one hand, the HO does not break the rotational symmetry, so our results are not conducive to those theoretical proposals that require the rotational symmetry breaking.[44–48] On the other hand, the proposed HO order parameter should be coupled to the B_{2g} channel due to the symmetry constraint revealed by our measurements. It may be a requisition for a theory to study the proposed order parameter in the presence of a slight lattice distortion along the (110) direction.

In conclusion, we have realized that there are no nematic fluctuations in URu$_2$Si$_2$ and a large residual $\zeta_{(110)}$ exists at 0 K. The latter is the unique feature to the HO since it is not found in the LMAFM state. Our results suggest that the HO can exhibit large anisotropic response to the uniaxial pressure or strain without rotational symmetry breaking, which could provide an interesting perspective in searching the order parameter of the HO.
