Motivated by the premise that superconductivity in iron-based superconductors is unconventional and mediated by spin fluctuations, an intense research effort has been focused on characterizing the spin-excitation spectrum in the magnetically ordered parent phases of the Fe pnictides and chalcogenides. For these undoped materials, it is well established that the spin-excitation spectrum consists of sharp, highly dispersive magnons. The fate of these high-energy magnetic modes upon sizable doping with holes is hitherto unresolved. Here we demonstrate, using resonant inelastic X-ray scattering, that optimally hole-doped superconducting Ba0.6K0.4Fe2As2 retains well-defined, dispersive high-energy modes of magnetic origin. These paramagnon modes are softer than, though as intense as, the magnons of undoped antiferromagnetic BaFe2As2. The persistence of spin excitations well into the superconducting phase suggests that the spin fluctuations in Fe-pnictide superconductors originate from a distinctly correlated spin state. This connects Fe pnictides to cuprates, for which, in spite of fundamental electronic structure differences, similar paramagnons are present.

Results

Dispersive high-energy magnons in parent BFA. To measure spin excitations in parent BFA and superconducting BKFA Fe-pnictide samples, we employ RIXS, which has recently been established as a powerful probe of the dispersion of magnetic excitations in a wide energy-momentum window. Many studies on undoped parent cuprates have demonstrated the sensitivity of RIXS to single-magnon excitations\(^1\) and collective orbital excitations\(^{17}\). Doped superconducting cuprates exhibit intense paramagnons, damped spin excitations over much of the BZ with dispersions and spectral weights closely similar to those of magnons in undoped AF ordered parent systems\(^{11,19}\).

The BFA and BKFA samples used in our RIXS experiments are single crystals grown using the self-flux method\(^{22,23}\). Resistivity and bulk magnetic susceptibility measurements demonstrate the high quality of all samples (see Supplementary Fig. S1). Figure 1a,b displays the schematics of the RIXS experimental geometry, as well as the reciprocal space that can be reached with Fe L\(_3\) RIXS. A typical Fe L\(_3\) edge X-ray absorption spectrum of BFA is shown in Fig. 1c, in good agreement with a previous report\(^{24}\). In Fig. 1d,e, a set of momentum-resolved Fe L\(_3\) RIXS spectra of BFA using \(\pi\) polarized incoming light at (0, 0), (0.5, 0) and (0.35, 0.35) in the BZ are displayed. All these spectra exhibit intense Fe 3d fluorescence at around \(-2\) eV energy transfer, which has been observed in RIXS studies on other Fe pnictides\(^{24}\) and chalcogenides\(^{25}\). In addition to these previous investigations\(^{24,25}\), we reveal near the BZ edges well-defined momentum dispersive excitations centered around 200 meV next to the quasi-elastic peak in the vicinity of zero energy.

In Fig. 2a,b, we show two sets of Fe L\(_3\) RIXS spectra of BFA with the momentum transfer directed along two high-symmetry directions, (0, 0)–(1, 0) and (0, 0)–(1, 1). All RIXS spectra for both BZ directions display well-defined excitations within an energy range of 0–300 meV superimposed on the tail of the Fe 3d fluorescence. For high-momentum transfer \(q\), these excitations clearly separate from the quasi-elastic peak. Approaching the \(\Gamma\) point, the excitation intensity decreases and the energy position shifts towards the quasi-elastic peak. To quantitatively analyze these excitations, we subtract the fluorescence background employing the method introduced in Hancock et al\(^{25}\) and decompose the spectral response close to the quasi-elastic peak (see Supplementary Fig. S2). As demonstrated in Fig. 2c, the excitation at the boundary peaks at around 200 meV and contains a high-energy tail.

In Fig. 2d,e, we show that the corresponding sets of excitations clearly disperse as a function of transferred momentum after subtraction of background and quasi-elastic peak. For the RIXS spectra excited with \(\sigma\) polarized incoming light, the excitation intensity is slightly suppressed. Furthermore, the spectral weight is almost quenched when the incident energy moves away from the Fe L\(_3\) resonance (see Supplementary Fig. S3). This observation is representative for single-magnon excitations as revealed with Cu L\(_3\) RIXS for many cuprates\(^{17,16–19}\). Unlike the parent cuprates, which are long-range ordered AF Mott insulators, the Fe-pnictide parent compounds are AF ordered spin-density wave semi-metals with compensating electron- and hole-like Fermi-surface pockets involving several Fe 3d orbitals. Thus, charge excitations (electron–hole pair excitations) can fall in the same energy window as spin excitations\(^{26}\). However, the electron–hole continuum is expected to be temperature independent\(^{27}\). In contrast, our RIXS measurements clearly revealed that the sharp excitations in the AF phase become much less well defined in the paramagnetic phase, thereby strongly suggesting the magnetic origin of these excitations (see Supplementary Fig. S4).

Comparison of our RIXS data for the parent BFA with available inelastic neutron scattering (INS) results clearly shows that the inelastic X-ray response is dominated by magnetic excitations, which is not unexpected as in direct RIXS spin-flip scattering is strong\(^{28,29}\). Fits to the inelastic response with an asymmetrical Lorentzian line shape convoluted with a Gaussian resolution function give a good description of the data\(^1\) (see Supplementary Fig. S2). In Fig. 2f, we plot the dispersion of the RIXS peak energy position as a function of momentum transfer. To exclude the effect of sample-dependent variations, we confirmed these results with independent measurements on additional samples. On top of RIXS peak positions, we overlay the dispersion curve of spin excitations extracted from INS measurements on a BFA parent sample\(^{30}\) (see Supplementary Discussion). The excellent agreement between INS and our RIXS data indicates on a simple phenomenological basis that indeed the dispersing excitations in the inelastic response are of magnetic origin. This conclusion is further supported by the fact that the line shape of the excitations can be well fitted using the formula describing the imaginary part of the dynamical spin susceptibility.
Closer comparison with the INS study on parent BFA\textsuperscript{30} demonstrates, furthermore, that our RIXS data show comparable half width at half maximum (HWHM) of the spin excitations, that is, damping (around 100 meV) at the zone boundary (see Fig. 4b).

**Persistent high-energy paramagnons in optimally hole-doped BKFA.** Having demonstrated that Fe L\textsubscript{3} RIXS allows to measure the dispersion of spin excitations in the AF ordered state, we are well prepared to further explore how spin excitations evolve in the superconducting (SC) phase. We focus now on an optimally hole-doped BKFA superconductor ($T_{c} = 39$ K), for which high-energy spin excitations have not been reported so far. By performing the same measurements as for BFA, the two corresponding sets of RIXS spectra along (0, 0)–(1, 0) and (0, 0)–(1, 1) BZ directions of BKFA are obtained and displayed in Fig. 3a,b. Remarkably, similar to BFA, BKFA also shows pronounced and well-defined excitations persisting up to 150 meV. Because these follow the same polarization and incident energy dependences as parent BFA and appear as smoothly connected to the magnetic excitations, that is, damping (around 100 meV) at the zone boundary (see Fig. 4b).

**Discussion**

From the comparison in Fig. 4a, it is noticeable that the spin-excitation energies in BKFA get softened relative to the ones in BFA. Softening of spin excitations upon doping has been observed in cuprates both in RIXS\textsuperscript{31} and INS\textsuperscript{32} studies. Moreover, doping induces damping of the spin excitations in cuprates because of the interaction with electron–hole excitations. Interestingly, doping of parent BFA does not create visible further damping of spin excitations (Fig. 4b). The line width of around 100 meV HWHM is likely intrinsic, because it is nearly two and half times the total instrumental resolution of our RIXS experiment (HWHM $\sim$ 40 meV). The observed large broadening...
of spin excitations already in the parent pnictide differs significantly from the situation of the parent cuprates. In the latter case, the RIXS instrumental resolution defines the single-magnon line width because of the long magnon lifetime. The larger observed magnon line width in the parent Fe pnictide is, however, not unexpected because its spin excitations, despite being well defined, are essentially damped by the interaction with itinerant electrons due to its metallic nature. Carrier doping into the SC state does not necessarily add further damping of spin excitations, consistent with our RIXS observation. Such different damping behaviour of the spin excitations demonstrates that Fe pnictides indeed deviate in this point from the strongly localized antiferromagnetism in cuprates, which can be ideally described by the Heisenberg model. We further notice that the total spin-excitation spectral weight is largely preserved when crossing from the AF to the SC phase. The same effect has been discovered in a RIXS study on the YBa$_2$Cu$_3$O$_{7-x}$ family, where well-defined dispersive paramagnons are also present and their integrated spectral weight persist in parent, under- and slightly overdoped compounds. Although pnictides and...
reciprocal lattice units are calculated based on the orthorhombic notation with the same lattice parameters as for the AF ordered BFA. The error bars represent s.d. of the fitting (the same as for b and c). (b, c) HWHM (damping) and integrated intensity of spin excitations of BFA and BKFA. The horizontal dotted line in b marks the HWHM of the total instrumental resolution of the RIXS experiment (40 meV).

Methods

Samples and experiments. The high-quality single crystals of BFA and BKFA used in the current study were grown by the flux method as described in Chen et al. and Zhang et al. High-resolution RIXS experiments were performed using the SAXES spectrometer at the Advanced Resonant Scattering (ADRESS) beamline of the Swiss Light Source, Paul Scherrer Institut, Switzerland. The energy and momentum resolutions were 40 meV (HWHM) and 0.01 Å⁻¹, respectively. Samples were cleaved in situ and measured in a working vacuum better than 5·10⁻¹⁰ mbar. All samples were aligned with the surface normal (001) in the scattering plane. X-ray absorption was measured using the total electron yield method by recording the drain current from the samples. For RIXS measurements, linear polarized X-rays were used with the incident energy tuned to 708 eV at the Fe 3d fluorescence peak. Measurements were conducted at room temperature (0.5 K) using a polychromator with a spectral resolution of 1 meV at the energy regions above Fe 3d fluorescence background and quasi-elastic peak subtraction. In the above formula, \( o \) is the energy transfer, \( 2e^{-\omega} \) represents the slope of the energy region above \(-1 \text{ eV}\), \( \beta e^{i\omega} \) and \( \gamma e^{i\omega} \) are exponential tails, whereas \( g_{\perp} \) gives rise to a smooth cross-over from the quasi-linear to the exponential region with a width \( G_{\perp} \) at the energy \( o_{\perp} \). The quasi-linear peak is fitted with two energy resolution limited Gaussian functions (Supplementary Fig. S2) accounting for elastic and phonon contributions.

Fe 3d fluorescence background and quasi-elastic peak subtraction. In order to fit the Fe 3d fluorescence line, we applied the procedure introduced in the analysis of RIXS spectra from a FeTe compound with similar fluorescence contribution:

\[
I_{\text{flu}} = I_{\text{flu}}(ze^{-\omega} \left( o \left( 1 - g_{\parallel} \right) + \beta e^{i\omega} g_{\parallel} + \gamma e^{i\omega} g_{\parallel} \right))
\]

(1)

In the above formula, \( o \) is the energy transfer, \( ze^{-\omega} \) represents the slope of the energy region above \(-1 \text{ eV}\), \( \beta e^{i\omega} \) and \( \gamma e^{i\omega} \) are exponential tails, whereas \( g_{\parallel} \) gives rise to a smooth cross-over from the quasi-linear to the exponential region with a width \( G_{\parallel} \) at the energy \( o_{\parallel} \). The quasi-linear peak is fitted with two energy resolution limited Gaussian functions (Supplementary Fig. S2) accounting for elastic and phonon contributions.

Fitting of the spin excitations. The spin-excitation spectra in RIXS are fitted using the imaginary part of the system’s spin susceptibility \( \chi'(q, \omega) \) (ref. 11). Because the spin excitations of the parent BFA are intrinsically broadened by the finite lifetime, we use for the RIXS fitting an asymmetrical Lorentzian function convoluted by the Gaussian resolution function:

\[
\chi'(q, \omega) = \frac{\Gamma_q}{(\omega - \omega_0)^2 + \Gamma_q^2} - \frac{\Gamma_q}{(\omega + \omega_0)^2 + \Gamma_q^2}
\]

(2)

In the above, \( \omega_0 \) and \( \Gamma_q \) stand for the peak energy and half width at half maximum of the spin excitation (that is, damping term), respectively. This formula is also employed for the fitting of the spin-excitation data from BKFA. Examples of the fitting procedure are given in Supplementary Fig. S2.

Normalization and integration of spin excitations. All RIXS spectra are normalized to the integrated Fe 3d fluorescence intensity in an energy-transfer window of \(-8 \text{ to } -1 \text{ eV}\). As the incident energy is always fixed at the Fe 1s resonance, the Fe 3d fluorescence intensity can be used as reference for the normalization. For the integration of the spin-excitation spectral weight, we use an energy-transfer window of \(-0.6 \text{ to } 0.0 \text{ eV}\) for all RIXS spectra. Below \(-0.6 \text{ eV}\), the spectral weight from the spin excitations is negligible.

Calculation of the spin-excitation dispersion curve. For understanding the momentum dispersion of the spin excitations in the RIXS spectra, we compare the spin-excitation dispersion curve of the INS data of a BFA parent compound with those of the parent BFA with different doping levels. The spin-dispersion curve from INS is reproduced using the same Heisenberg Hamiltonian consisting of effective in-plane nearest-neighbour \( (J_1, \Gamma_1) \), next-nearest-neighbour \( (J_2) \) and out-of-plane \( (J_c) \) exchange interactions as in Zhao et al. The dispersion relations are given by:

\[
A_{qz} = 2S J_1 \left( \cos(\pi K) - 1 \right) + J_1 + 2J_2 + J_c
\]

(3)

\[
B_{qz} = 2S J_1 \cos(\pi J_1 K) + 2J_2 \cos(\pi J_1 K) + J_c \cos(\pi J_1)
\]

(4)

In the above relations, \( J_z \) is the single ion anisotropy constant and \( q_z \) is the reduced momentum transfer away from the AF zone center (1, 0, 1). (H, K, L) is defined as \((q_x/2 \pi, q_y/2 \pi, q_z/2 \pi)\) in which \( a = 5.62 \text{ Å}, b = 5.57 \text{ Å} \) and \( c = 12.97 \text{ Å} \) are the orthorhombic unit cell-lattice parameters in the spin-density wave phase. To calculate the dispersion curve for the momentum space covered in our RIXS experiment, we use the fitted exchange values from Harriger et al. in which \( S_{1A} = 59.2 \pm 2.0, S_{1B} = -9.2 \pm 1.2, S_{2A} = 13.6 \pm 1.0, S_{2B} = 1.8 \pm 0.3 \text{ meV and } J_1 = 1.0 \). L is fixed to 1.0 as only negligible dispersion contributes at the center for other \( L \) values. We also take into account the twinning of domains in obtaining the dispersion curves along both directions. As is shown in the main text, our RIXS data are in excellent agreement with the spin-excitation dispersion curve obtained from INS within error bars.

When sampling the in-plane momentum transfer \( q_x \) by varying the incidence angle only, the out-of-plane value \( q_{\text{in-plane}} \) is also changing. However, we verified in our analysis that the influence of \( q_{\text{in-plane}} \) on the in-plane spin wave dispersion shows no difference at the boundaries and only a very small (<10 meV) dispersion at the center, which is negligible compared with our energy resolution (see Supplementary Fig. S5).

Figure 4 | Summary of spin excitations of BFA and BKFA. (a) Dispersion of spin excitations of BFA in AF phase, and BKFA in SC phase. For BKFA the reciprocal lattice units are calculated based on the orthorhombic notation with the same lattice parameters as for the AF ordered BFA. The error bars represent s.d. of the fitting (the same as for b and c). (b, c) HWHM (damping) and integrated intensity of spin excitations of BFA and BKFA. The horizontal dotted line in b marks the HWHM of the total instrumental resolution of the RIXS experiment (40 meV).
